Humoral immune responses are typically characterized by primary IgM antibody responses followed by secondary antibody responses associated with immune memory and comprised of IgG, IgA and IgE. Here we measured acute humoral responses to SARS-CoV-2, including the frequency of antibody-secreting cells and the presence of SARS-CoV-2-specific neutralizing antibodies in the serum, saliva and broncho-alveolar fluid of 159 patients with COVID-19. Early SARS-CoV-2-specific humoral responses were dominated by IgA antibodies. Peripheral expansion of IgA plasmablasts with mucosal-homing potential was detected shortly after the onset of symptoms and peaked during the third week of the disease. The virus-specific antibody responses included IgG, IgM and IgA, but IgA contributed to virus neutralization to a greater extent compared with IgG. Specific IgA serum concentrations decreased notably one month after the onset of symptoms, but neutralizing IgA remained detectable in saliva for a longer time (days 49 to 73 post onset). These results represent a critical observation given the emerging information as to the types of antibodies associated with optimal protection against re-infection, and whether vaccine regimens should consider targeting a potent but potentially short-lived IgA response.

INTRODUCTION

In December 2019, a novel coronavirus named SARS-CoV-2 (Severe Acute Respiratory Syndrome Coronavirus 2) was identified as the cause of an acute respiratory disease known as coronavirus disease 19 (COVID-19). This enveloped positive-sense RNA virus is a member of the betacoronavirus and spread worldwide with an unprecedented speed compared with the dissemination of SARS-CoV in 2003 and Middle East respiratory syndrome-related coronavirus virus (MERS-CoV) in 2012 (1). Recent reports indicate that SARS-CoV-2 elicits robust humoral immune responses, including production of virus-specific antibodies of the IgM, IgG, and IgA isotypes. Patients have been shown to achieve seroconversion and produce detectable antibodies within 20 days of symptom onset, although the kinetics of IgM and IgG production are variable (2–3).
Secretory IgA plays a crucial role in protecting mucosal surfaces against pathogens by neutralizing respiratory viruses or impeding their attachment to epithelial cells (5–8). Influenza-specific IgA has been shown to be more effective in preventing infections in mice and humans compared with influenza-specific IgG, and elevated IgA serum levels have been correlated with influenza vaccine efficacy (9–11). IgA may also play an important role in SARS-CoV infection. In mice, intranasal vaccination with SARS-CoV proteins induces localized and systemic virus-specific IgA responses and provides better protection against SARS-CoV-CoV challenge compared with intramuscular delivery, suggesting that mucosal-induced IgA is protective (12). A recently reported intervention based on an intranasal immunization with a MERS-derived vaccine confirmed a beneficial role of IgA (13). However, the role of virus-specific IgA against natural SARS-CoV-2 infection in humans remains poorly understood.

We tracked antibody-secreting cells, characterized here as plasmablasts, in the blood of SARS-CoV-2-infected patients. We measured specific antibody titers longitudinally in serum and compared the neutralizing capacities of purified serum monomeric IgA and IgG. Finally, we studied the neutralization potential of mucosal antibodies present in lower respiratory tract pulmonary secretions and saliva. Our results show that human IgA antibodies are often detectable before the appearance of SARS-CoV-2-specific IgG and suggest a role for IgA antibodies in early virus neutralization.

RESULTS
Circulating plasmablasts preferentially express IgA1
The rapid and transient appearance of plasmablasts in peripheral blood is a common feature of the acute phase of viral infections (14). We monitored phenotypic changes of B cells longitudinally in the blood of 38 SARS-CoV-2-infected patients (Table S1) using flow cytometry. Plasmablasts are immature antibody-secreting cells, defined here as proliferating cell cycling Ki67+CD19lowCD27highCD38high cells (Fig. 1A-S1A). The proportion of plasmablasts in the B cell compartment increased significantly at days 1 to 9 after the onset of symptoms (median[0.9-17.8]% vs 0.5[0.1-1.5]%); p=0.0008) in healthy donors; n=21 and n=9, respectively; Fig. 1B), peaked between days 10 to 15 (11.8[0.7-62.1]%), n=28, Fig. 1B) and then decreased (4.4[0.2-33.8]% between day 16 to 25, n=21; 0.5[0.1-3.2]% after day 50, n=14; Fig. 1B). Longitudinal follow-up in 7 patients also confirmed the transient nature of plasmablasts expansion during acute viral infection (Figure S1B).

We analyzed circulating plasmablasts for surface expression of CCR10, a chemokine receptor involved in the migration of immune cells to mucosal sites, especially the lung (15, 16). Less than 10% of memory and naive B cells, but approximately 40% of detected plasmablasts, were CCR10+ (3.8[1.2-9.6]% in naive B cells vs 10.9[4.1-47.7]% in memory B cells vs 34.9[20.7-83.4]% in plasmablasts; n=25; Fig. 1C), suggesting a potential lung tissue tropism of the latter. Analysis of the early phase of the immune response revealed only a minor population of plasmablasts that produced IgM, as measured by intracellular staining (10.5[4.2-54.1]% IgM+ plasmablasts; n=17; Fig. 1D). In contrast, most plasmablasts expressed IgA (61.4[18.1-87.6]% IgA+ plasmablasts vs 27.9[7.4-64.8]% IgG+ plasmablasts; n=17; Fig. 1D), a feature consistent with plasmablasts that are found at mucosal sites. Intracellular IgA subclass identification showed higher frequencies of IgA1-expressing plasmablasts, as compared with IgA2 (66[26.8-88.5]% IgA1+ vs 31.6[3.7-70.8]% IgA2+ in IgA+ plasmablasts; n=13; Figure S1C-D). This first wave of circulating IgA-expressing plasmablasts peaking between day 10 and day 15, was followed by a second wave of IgG-expressing cells that were more dominant by day 22 after the onset of symptoms (Fig. 1E, S1E-F). The majority of IgA+ plasmablasts expressed CCR10, but this chemokine receptor was expressed by a minority of IgG+ plasmablasts (60.5[37.6-92.6]% vs 23.3[3.2-78]% CCR10+, n=15; Figure SIG), suggesting that the latter may occupy a different niche, such as the bone marrow. Of note, the frequency of peripheral IgM-expressing plasmablasts did not vary significantly at early time points (Figure S1H) and only marginally at later time points (Figure S1I).

In a recent study that characterized the immune response of a COVID-19 patient, the induction of T follicular helper (Tfh) cells was reported to occur concomitantly with that of plasmablasts (17). In order to evaluate a potential germinal center origin of the plasmablast wave observed in our patients, we tracked CD4+CXCR5+PD1+ Tfh cells longitudinally in their blood. We found no significant increase in the frequency of Tfh subsets in COVID-19 patients, as compared to healthy donors, at any of the analyzed time points (Figure S2A-B). The frequency of neither activated (CD4+CXCR5+PD1+), nor latent (CD4+CXCR5+PD1) Tfh cells was found to correlate with that of plasmablasts. (Figure S2C).

Taken together, these results point toward an early humoral response to SARS-CoV-2 dominated by IgA-expressing plasmablasts that have phenotype consistent with plasmablasts found at mucosal sites.

Early SARS-CoV-2-specific IgA detection
We assessed the prevalence of IgG, IgA and IgM antibodies recognizing the SARS-CoV-2 full-length nucleocapsid protein (NC) or spike receptor-binding domain (RBD) in serum samples from 132 infected patients (Tables S2 and S3) using a photonic ring immunoassay, which can measure the level of antibodies to multiple antigens simultaneously (Figure S3) (18, 19).

Data presented in Fig. 2B suggested that serum anti-RBD IgA might be detected earlier than anti-RBD IgG. In the
subset of patients monitored at the very early time points following disease onset (first 7 days post-symptoms, n=48), anti-RBD IgA and IgG were detected in 15 and 7 samples, respectively, at concentrations that did not reach statistical significance (positive samples: 31% IgA vs 15% IgG, p=0.052; calculated from data presented in Fig. 2A-B and Figure S4A), whereas the positive rates of anti-NC were similar regardless of isotype (positive samples: 23% IgA vs 15% IgG, p=0.43; Fig. 2B). However, in a subset of patients monitored at multiple time points (n=38), time to positivity is significantly shorter for anti-RBD IgA than IgG (12[3-24] vs 15[8-24] days, p=0.03, Figure S4B). IgM is typically considered a marker of acute infection, but anti-RBD IgM were detected only in 7 out of these 48 early samples (Fig. 2A). Moreover, anti-NC IgM remained undetectable in all samples except one. These results suggest that serum anti-RBD IgA is likely to be detected earlier than anti-RBD IgG.

The proportion of patients with detectable anti-RBD IgG increased until hitting a plateau around the fourth week post-symptom onset (positive samples: 15% day 1-7; 42% day 8-14; 74% day 15-21; 90% day 22-28 and 92% day>28; Fig. 2A-B). In contrast, the frequency of patients with anti-RBD IgA peaked around day 22 (positive samples: 31% day 1-7; 51% day 8-14; 72% day 15-21 and 80% day 22-28; Fig. 2A-B), then decreased by day 28 (positive samples: 23% day>28; Fig. 2A-B). Following similar kinetics with respect to the appearance of anti-RBD antibodies, the proportion of patients with detectable anti-NC IgG remained stable around the fourth week post-symptom onset (positive samples: 15% day 1-7; 56% day 8-14; 85% day 15-21; 90% day 22-28 and 89% day>28; Fig. 2A-B) whereas anti-NC IgA quickly disappeared and were no longer detectable in most patients one month after disease onset (positive samples: 23% day 1-7; 52% day 8-14; 67% day 15-21; 65% day 22-28 and 8% day>28 ; Fig. 2A-B). Of note, in two patients who recovered from COVID-19, no specific antibodies were detected at day 32 and day 47 (Fig. 2A).

Both anti-RBD and anti-NC IgG titers increased over time (anti-RBD arbitrary units/mL: 3.6[0.1-102.1] day 1-7; 8.3[0.2-145.2] day 8-14; 32.6[3.5-168.9] day 15-21; 36.5[18-200.9] day 22-28; 57.9[5.1-209.9] day>28; anti-NC arbitrary units/mL: 2.4[0.1-138.2] day 1-7; 15.2[0.1-219.8] day 8-14; 61.7[0.1-201.7] day 15-21; 103.5[0.1-236.2] day 22-28; 82.4[0.1-200.2] day>28; Fig. 2A) whereas virus-specific IgA titers increased during the first 3 weeks post-symptom onset, then dropped and were undetectable one month after recovery (anti-RBD arbitrary units/mL: 3.7[0.1-69.6] day 1-7; 5.2[0.1-166.3] day 8-14; 9.5[0.1-58.5] day 15-21; 7.3[0.1-149.9] day 22-28; 3.1[0.1-26.4] day>28; anti-NC arbitrary units: 0.1[0.1-153.7] day 1-7; 3.9[0.1-158.2] day 8-14; 25.5[0.1-128.2] day 15-21; 6.9[0.1-116.6] day 22-28; 0.1[0.1-11.9] day>28; Fig. 2A).

These results suggest that anti-SARS-CoV-2 IgA testing may improve early COVID-19 diagnosis, but serum testing more than 28 days after the onset of symptoms may only reliably detect IgG antibodies.

**Early SARS-CoV-2-specific IgA response is not associated with COVID-19 severity**

We explored the relationship between virus-specific serum Ig titers and the clinical course of patients with COVID-19. We focused the analysis on early serum samples obtained no later than ten days after the onset of clinical symptoms. A composite endpoint was used to define severe COVID-19 in patients that were initially admitted to the same non-intensive care unit (ICU) internal medicine ward and included the following criteria: transfer to the ICU, use of oxygen therapy by nasal cannula above 5 L/min, high-flow nasal cannula oxygen therapy, invasive or non-invasive mechanical ventilation, severe acute confusional state, acute renal failure and death. Taken together, early virus-specific IgG, IgM and IgA titers were not dramatically different in severe patients compared with non-severe patients (Table S4).

**Serum IgA is a potent and early SARS-CoV-2 neutralizing agent**

We sought to determine the contribution of each of the IgG and IgA isotypes to virus neutralization. We assessed the neutralizing capacity of serum antibodies using a pseudonutralization assay. We tested the neutralization potential of serum at a dilution of 1/40, which rapidly increased during the course of disease and plateaued by day 10 post-symptom onset (Fig. 3A). Pseudovirus neutralizing activity varied considerably between patients, with half maximal inhibitory concentration (IC50) values ranging from 1/109 to 1/16189 serum dilution (Fig. 3B). We compared the pseudotyped particle entry inhibition assay with a whole virus neutralization assay based on the utilization of a live SARS-CoV-2 field isolate (Figure S5A), and we found a strong correlation between results obtained using these two assays (r=0.88, p<0.0001), which is consistent with other published findings (20, 21).

We then sought to define the respective contributions of the dominant antibody isotypes to virus neutralization by using purified IgA and IgG fractions from the sera of 12 patients (Figure S5B) that were tested in parallel using the pseudovirus neutralization assay (Fig. 3C, D). Strikingly, IgA preparations were more potent in their neutralization compared with paired IgG (Fig. 3C-E). We observed that serum samples with low neutralization potential (light blue curves in Fig. 3B) also had low IgA-based neutralizing activity (corresponding light blue curves in Fig. 3D), and we confirmed that serum neutralization potential was only associated with anti-RBD IgA content and not anti-RBD IgG (Fig. 3F). IgA neutralization potential correlated directly with anti-RBD IgA serum titers (r=-0.88, p<0.0001; Figure S5C) but not with anti-NC IgA titers (r=0.14, p=0.58; Figure S5D), suggesting that IgA neutralization potential is closely linked to RBD binding. IgG is approximately five times more abundant in serum than...
IgA, but as shown, purified IgA fractions had approximately seven times lower IC50 values as compared with purified IgG ([min-max]; IgA IC50 [1.1–454.9] vs IgG IC50 [11.9–982.4]; n=18, Fig. 3E). In addition, the more efficient neutralization potential of IgA compared with IgG cannot be explained by an avidity effect, as both purified antibody preparations were monomeric (Figure S5B).

These results suggest that IgA contributes more than IgG to serum neutralization potential in the early phase of the infection. Of note, there are exceptions to this rule, such as patients #2 and #3, who both presented with very low anti-RBD IgA levels (below 11 AU/ml between day 6 and day 18) but instead mounted an early serum IgM response (Figure S5E).

**Mucosal IgA is a SARS-CoV-2 neutralizing agent**

These observations detail the contributions of IgA and IgG to systemic humoral immunity. However, the main SARS-CoV-2 targets are lung epithelial cells (22, 23), and mucosal immunity differs from systemic immunity. To assess local mucosal immunity, saliva and bronchoalveolar lavage (BAL) samples were also tested. IgG concentrations were consistently higher than IgA in the tested BAL samples, except for one patient (Figure S5F), but IgA concentrations are higher than IgG in saliva (median[min-max]; IgA 392[92–1200] vs IgG [70–130] μg/ml; n=10; Figure S5G). Consistent with these findings, previous reports demonstrated an increased IgG:IgA ratio along the respiratory tract, as measured from the nasal compartment to the lungs (24, 25). In contrast to serum-purified IgA, both monomeric and dimeric IgA were observed in bronchoalveolar fluids (Figure S5H). BAL samples were harvested at various times, including sampling as early as 4 days after symptom onset, and pseudovirus neutralization activity was detected in most samples (Fig. 3G). Anti-RBD IgA were detected in most BAL samples, whereas anti-RBD IgG were above the threshold of positivity in only half of samples (Figure S5I), suggesting that IgA may contribute more than IgG to SARS-CoV-2 neutralization in the lung. Although saliva samples were collected after day 49 post-symptom onset, 8 out of the 10 samples neutralized SARS-CoV-2-pseudotyped viral particles, albeit with notable inter-individual variability (Fig. 3H). Pseudovirus neutralization activity directly correlated with anti-RBD IgA titers (r=0.796, p<0.008; Fig. 3H) but did not correlate with anti-RBD IgG titers, although anti-RBD IgG were above the threshold of detection (Fig. 3H). Anti-RBD IgA were consistently more abundant in saliva than in serum (9.5[22.5–6.2] vs 5.2[4.3–6.8]; p=0.0039; Fig. 3I), suggesting that SARS-CoV-2-specific IgA may persist longer at mucosal sites compared with peripheral blood in hospitalized COVID-19 patients. Observations at later time points (days 189 to 230 post-symptoms) in a series of ambulatory individuals who had experienced pauci-symptomatic COVID-19 (Table S2) revealed no detectable neutralization activity in saliva (Figure S5J).

**DISCUSSION**

Our data highlight the potency of IgA in the early stage of COVID-19 disease at various body sites through the analysis of blood, BAL, and saliva. We show that SARS-CoV-2 neutralization is more closely correlated with IgA than IgM or IgG in the first weeks after symptom onset. Our own results do not directly imply that monomeric IgA would be inherently more neutralizing than monomeric IgG. However, published works already suggest that SARS-CoV-2-specific IgA and IgG responses are indeed qualitatively different. In recent study based on the same variable SARS-CoV-2-specific antibody domain, but expressed as IgA or IgG, Ejemel et al. showed that the IgA monomer had significantly enhanced neutralization potency over its IgG equivalent (26). It is proposed that the increased flexibility and longer hinge of IgA1, relative to IgG (27), would be more favorable to interactions between the IgA monomer and the SARS-CoV-2 spike trimer. Previous studies in influenza- and HIV-specific antibodies have reported similar observations (28).

Another possibility is that IgA may be more broadly cross-reactive against various human coronaviruses (HCoVs), as suggested from the extensive analysis of memory B cells of a survivor of the 2003 SARS-CoV outbreak (29). It is also possible that the maturation of the systemic IgG response may be slightly delayed compared with the mucosal IgA response. Our results show that serum IgA, particularly anti-RBD IgA, are detected earlier compared with IgG, and the dramatic plasmablast expansion that follows SARS-CoV-2 infection is dominated by IgA-secreting cells (Fig. 1D). The time to positivity against RBD is dramatically shorter for IgA than for IgG (Figure S4B), and serum neutralization potential is associated with anti-RBD IgA isotype antibodies (Figure S5F). We also observed a rapid decline in SARS-CoV-2-specific IgA serum levels, thereby bringing into question the long-term efficacy of this dramatic first wave response. In convalescent individuals, plasma SARS-CoV-2-specific IgA monomers were found to be two-fold less potent in neutralization assays than IgG equivalents (30). It is also possible that sustained SARS-CoV-2-specific secretory IgA levels are maintained in mucosal secretions, as we detected higher SARS-CoV-2-specific IgA titers in saliva relative to paired serum samples obtained after day 49 post-symptom onset (Fig. 3I). This observation is consistent with the finding that the dimeric form of IgA, which is found in the mucosa, is more potent against authentic SARS-CoV-2 than both IgA and IgG monomers (30). However, neutralizing activity was not detectable at later time points (days 189 to 230) in the saliva of 14 individuals who had exhibited mild, ambulatory, COVID-19 (Figure S5J).

Mucosal SARS-CoV-2-neutralizing antibodies may arise from multiple origins. Monomeric plasma IgA antibodies do...
not bind to FcRn but can reach the airways through an alternative receptor-independent process called transudation, which is more likely to occur in damaged lung tissue (31, 32). A clonal relationship has been shown between serum and mucosal antigen-specific IgA (33). We show that monomeric IgA are present in BAL, thus it is possible that plasma IgA antibodies could exert functions in the lower intestinal track as well. Whereas IgA and IgG may reach the airways and lungs by transudation from plasma, no significant correlation was observed between BAL and serum-specific antibody titers (Figure S5H), suggesting that a part of the SARS-CoV-2 antibody response is generated locally. Re-circulating IgA-secreting plasmablasts with a mucosal-homing profile (16, 34–36) were detected in high numbers in the patients we studied and are likely to seed the lung/airway interface. IgA-secreting cells can efficiently home to and reside within the mucosa (37), and IgA subclass switch recombination can take place in these tissues (38) in a T cell-independent manner (39). The lack of correlation between plasmablast and Tfh cell expansion observed in this study suggests that germinal center-independent induction of IgA is occurring (40). Of note, several recently described SARS-CoV-2 neutralizing IgG (41, 42) did not carry somatic mutations typically associated with affinity maturation and T cell help. A molecular and functional characterization of IgA monoclonal antibodies secreted by plasmablasts found in peripheral blood during the first week of symptom onset may shed light on their mutational status. The observations made in our study could provide insight into the observation that the vast majority of children develop mild symptoms or are asymptomatic upon SARS-CoV-2 infection (43, 44), by suggesting that cross-reactive IgA, recently identified in human gut mucosa against other targets than SARS-CoV-2 (34, 45), may be more prevalent in children and/or could be rapidly mobilized in response to infection with SARS-CoV-2.

We confirmed that both serum, BAL and saliva antibodies have SARS-CoV-2-neutralization potential using a pseudo-neutralization assay and validated with a viral neutralization assay. It remains to be confirmed whether this response is long lasting in patients who have experienced more severe disease compared with the ambulatory patients we tested in the present study. saliva analysis, potentially based on newly developed digital ELISA-based assays, such as the single molecule array (Simoa™) (46), may represent a convenient way to address this issue in future studies.

In several early serum samples with efficient virus neutralizing capacity, only anti-RBD IgM were detected at measurable amounts, as neither IgA nor IgG SARS-CoV-2 spike RBD-specific antibodies were above the threshold of detection (P2 day 14 and P3 day 6 post symptoms, Figure S5E). This observation suggests that IgM may provide some level of protection as well, but this sequence of detection of IgM first, followed by IgG and IgA is unusual and not likely to be prevalent. A more typical profile is exemplified by patient P9, with anti-RBD IgA levels peaking before the appearance of anti-RBD IgG and barely detectable IgM at any time point (Figure S5E). Because only virus-specific IgM are detected at early time points in rare cases, it remains to be determined if all isotypes should be measured during serological diagnosis.

It was recently proposed that high levels of IgA might play a detrimental role in COVID-19 patients (47). We compared early IgA levels in patients with subsequent favorable or severe outcomes. We show that early IgA levels were not significantly higher in patients that later deteriorated (Table S4). Our results therefore do not sufficiently support the hypothesis that an early IgA response might have a potential negative influence on disease progression.

Our study has several limitations. Given the time frame covered in this study, further longitudinal studies are needed to assess whether local SARS-CoV-2-specific IgA production persists for a longer time in patients recovered from severe COVID-19, than in the paucisymptomatic individuals we have been tested at late time points. In addition, it remains to be determined whether secretory antibodies may contribute to a longer-term barrier effect in the nose and lung compared with saliva.

In conclusion, our findings suggest that IgA-mediated mucosal immunity may be a critical defense mechanism against SARS-CoV-2 at the individual level that may also reduce infectivity of human secretions, and therefore viral transmission. This finding may also inform the development of vaccines that induce specific respiratory IgA responses to SARS-CoV-2.

MATERIALS AND METHODS

Study design

We performed a single-center study carried out at APHP-Sorbonne Université. The target population for the main study was composed of hospitalized, adult, SARS-CoV-2-infected, patients. Blood samples were obtained in a longitudinal manner from all COVID-19 patients admitted at E3M institute, Pitié-Salpêtrière hospital over a period of one month (from April 20th 2020 onwards). Healthy individuals, controlled SARS-CoV-2-negative (PCR and serology), were recruited among laboratory staff members. Samples were processed in the Department of Immunology (G. Gorochov), located on the same hospital site. Samples were analyzed in the same department, and aliquots were shipped at 4°C to the Pasteur Institute for Virological Studies. Serum and saliva samples were also obtained at later time points from hospital-discharged patients consulting in the Department of Internal Medicine (Z. Amoura) of the E3M Institute for planned post-COVID clinical check-ups. An ancillary study was performed in ambulatory health care workers that never
required hospitalization but had been exposed to SARS-CoV-2, as confirmed by PCR and/or serology.

**Patients recruitment and samples preparation**

Fresh blood sample from 135 consecutive adult patients with COVID-19 referred to the institute E3M, Pitié-Salpêtrière Hospital, Paris were included in the study between March 22, 2020 and April 24, 2020 and compared with 20 age and sex-matched healthy donors (HDs). The diagnosis of COVID-19 was confirmed for 125 patients, by SARS-CoV-2 carriage in the nasopharyngeal swab, as measured by real-time reverse transcription-PCR (real-time RT-PCR). The ten remaining patients had a negative nasopharyngeal SARS-CoV-2 real-time RT-PCR analysis but they all had clinical symptoms and a chest computed tomography (CT) scan highly evocative of COVID-19, and they all tested positive for the presence of serum anti-SARS-CoV-2 antibodies. Demographic and clinical characteristics are detailed in Tables S1-S3. To define a poor course of the disease after the admission and the first serum sampling, we used a composite endpoint including transfer to intensive care unit, use of oxygen therapy by nasal cannula above 5 L/minute, high-flow nasal cannula oxygen therapy, invasive or non-invasive mechanical ventilation, severe acute confusional state, acute renal failure and death. Broncho-alveolar lavages (BAL) were collected from 10 COVID-19 patients hospitalized in intensive care units at Pitié-Salpêtrière Hospital, Paris and compared with 3 COVID-19-negative samples. Demographic and clinical characteristics are detailed in Tables S5. All patients gave informed consent. This study was approved by the local ethical committee of Sorbonne Université (n°2020-CER2020-21). For all patients, sera were stored immediately after collection at -80°C. Peripheral blood mononuclear cells (PBMCs) were isolated from the blood samples of 38 patients after Ficoll-Hypaque density gradient centrifugation (Eurobio, Courtabœuf, France) and analyzed immediately. Clinical characteristics of these patients are presented in Table S1.

Saliva samples were self-collected by aspiration using a flexible Pasteur pipette (Fisher Scientific). Roughly 1 to 3 ml of saliva was collected into a sterile urine cup. All saliva samples were stored at 4°C and transported to the research lab of the Department of Immunology within 5 hours of sample collection and tested within 24 hours of sample collection.

**B cell and T cell phenotyping**

Phenotyping was assessed on freshly isolated PBMCs stained with a combination of anti-human antibodies (Table S6). Intracellular staining was performed on fixed and permeabilized cells (using the FOXP3 Transcription Factor Staining Buffer kit, eBioscience). Cells were acquired on a BD FACSCanto II Flow cytometer (BD biosciences) and analyzed with FlowJo v10 software (FlowJo, LLC).

**Serological analysis**

SARS-CoV-2 specific IgA, IgM and IgG antibodies were measured in 214 serum samples from 132 patients with The Maverick SARS-CoV-2 Multi-Antigen Serology Panel (Genalyte Inc. USA) according to the manufacturer's instructions. The Maverick SARS-CoV-2 Multi-Antigen Serology Panel (Genalyte Inc) is designed to detect antibodies to five SARS-CoV-2 antigens: nucleocapsid, Spike S1 RBD, Spike S1S2, Spike S2 and Spike S1, with in a multiplex format based on photonic ring resonance technology (18, 19). This automated system detects and measures with good reproducibility (Figure S3) changes in resonance when antibodies bind to their respective antigens on the chip. Combined IgG and IgM antibodies showed 91% sensitivity and 98% specificity. Briefly, 10 µl of each serum sample was added to a sample well plate array containing required diluents and buffers, and the plate and chip were loaded in the instrument for chip equilibration with the diluent buffer to measure baseline resonance. The serum sample is then charged over the chip to bind specific antibodies to antigens present on the chip. The chip is then washed to remove low affinity binders, and specific antibodies are detected with anti-IgG, -IgA or -IgM secondary antibodies. 43 sera collected before December 2019 were analyzed to calculate cut-off values. Positivity was defined as results above the 99th percentile.

**Purification and quantification of IgA and IgG from serum**

IgA and IgG were isolated from 12 serum samples diluted in 1X-PBS as previously described (45). Sera were selected after SARS-CoV-2-specific antibody evaluation. Briefly, serum samples were load onto peptide M/agarose or protein G/agarose column (Invivogen) after column equilibration. Chromatography steps were performed at a flow rate of 0.5ml/min. Next, 20 column volumes of IX-PBS were used to wash the column. IgA and IgG were then eluted with 5 ml of 0.1M glycine (pH 2-3, Sigma-Aldrich) and pH was immediately adjusted to 7.5 with 1M Tris. IX-PBS buffer exchange was achieved using Amicon® Ultra centrifugal filters (Merck Millipore) through a 100-kD membrane according to the manufacturer’s instructions. The quantification of IgA and IgG was determining using NanoVue Plus microvolume spectrophotometers. The purity of the IgG and IgA fractions was assessed by ELISA (IgG, IgM and IgA ELISA quantitation set, Bethyl), according to the manufacturer’s recommendations. Undesirable isotypes (IgM and IgA/IgG counterparts) represented less than 1% of the purified immunoglobulins. Electrophoresis was then used to detect Ig monomers and dimers. Purified Ig (1μg) was separated using 4%-20% polyacrylamide gel (Mini-PROTEAN TGX Stain-Free Precast Gels; Bio-Rad) in native conditions (Laemmli 4X, Bio-Rad). Gels were incubated with Imperial™ Protein Stain (Thermoscientific) and washed 5 times with water.
Pseudovirus production and permissive cell line generation

Pseudotyped vectors were produced by triple transfection of 293T cells as previously described (48). Briefly, cells were cotransfected with plasmids encoding lentiviral proteins, a luciferase Firefly reporter, and plasmid expressing a codon-optimized SARS-CoV-2 spike (S) gene. Pseudotyped vectors were harvested at day 2 post-transfection. Functional titer (TU) was determined by qPCR after transduction of a stable Human Embronic Kidney (HEK) 293T-hACE2 cell line. To generate this cell line, HEK 293T cells were transduced at a multiplicity of infection (MOI) of 20 with an integrative lentiviral vector expressing human angiotensin converting enzyme 2 (ACE2) gene under the control of the ubiquitin C promoter. Clones were generated by limiting dilution and selected on their permissivity to SARS-CoV-2 S-pseudotyped lentiviral vector transduction.

Pseudoneutralization Assay

Serum dilutions were mixed and co-incubated with 300 transducing units (TU) of pseudotyped vector at room temperature for 30 min. Serum, BAL or saliva and vector were then diluted in culture medium (DMEM-glutamax (Gibco) + 10% FCS (Gibco) + penicillin/streptomycin 1% (Gibco). This mixture was then plated on tissue culture-treated black 96-well plates (Costar) with 20,000 HEK 293T-hACE2 cells per well in suspension. To prepare the suspension, cell flasks were washed with DPBS twice (Gibco) and a single-cell suspension was made in with DPBS + 0.1% EDTA (Promega) to preserve integrity of hACE2 protein. After 48h, the medium was removed from each well and bioluminescence was measured using a luciferase assay system (Promega) on an EnSpire plate reader (PerkinElmer).

Neutralization Assay

U2OS-ACE2 GFP+10 and GFP1 cells, also referred to as S-Fuse cells (21), were mixed (1:1 ratio) and plated at 8x10^3 cells per well in a 96-well flat-bottom plate (μClear, #655090) 24 hours before infection. Cells were then infected with SARS-CoV-2 (strain BetaCoV/France/IDF0372/2020) at an MOI of 0.1. At 18 hours post-infection, cells were fixed in 4% PFA for 30 min at room temperature, washed, and resuspended in PBS containing Hoechst 33342 (1:10000). Images were acquired on an Opera Phenix High Content Screening System (PerkinElmer) and analyzed on Harmony High-Content Imaging and Analysis Software.

Immunoblotting

BALs were concentrated (5X) using a 100-kd membrane (Amicon® Ultra centrifugal filters; Merck Millipore). Samples were diluted with 4X Laemml sample buffer (BioRad) and heated at 95°C for 5 min. Proteins were separated using 4%-20% polyacrylamide gel electrophoresis (Mini-PROTEAN TGX Stain-Free Precast Gels; Bio-Rad) for 30 min at 200V and then were transferred to nitrocellulose for Western blot analysis. Human IgA was detected with horseradish peroxidase-conjugated goat anti-human IgA used at a 1:20,000 dilution for 1 hour (Bethyl Laboratories) followed by the addition of Enhanced Chemi-Luminescence (ECL) substrate (Clarity™ Western ECL, Bio-Rad). Chemiluminescence was visualized with a camera system (ImageQuant™ LAS4000, GE Healthcare). All incubations were in 1X-PBS with 5% non-fat milk, and wash steps used 1X-PBS with 0.1% Tween.

Statistical analysis

Variables were expressed as the median. Several nonparametric tests were used including, the Mann-Whitney U test to compare two independent groups, the Wilcoxon test to compare paired values, and the chi-square test to compare antibody positive rates. The spearman correlation test was used to measure the correlation between two variables. Statistics were corrected for multiple comparisons with Dunn’s test. Significant P-values are indicated as described: * p < 0.05; ** p < 0.01; ***p < 0.001; ****p < 0.0001. Statistical analysis was performed using GraphPad Prism software, V6 (GraphPad, San Diego).

Medline
Fig. 1. Plasmablast dynamics following SARS-CoV-2 infection. A. Representative flow cytometry analysis of B cell subpopulations in the blood of SARS-CoV-2 infected patients. Doublets and dead cells were excluded before CD3-CD19+ gating. Plasmablasts are defined as CD19\text{low}CD27\text{high}CD38\text{high}Ki67+ cells, memory B cells as CD19+CD27+IgD-Ki67- and naïve B cells as CD19+CD27-IgD+Ki67- cells. B. Plasmablast frequency in B cell compartment in blood of SARS-CoV-2 infected patients (n=38, clinical characteristics in Table S1) compared with healthy donors (n=9). Histograms represent medians. P-values were calculated using Dunn’s multiple comparison test (* p<0.05; ** p<0.01; *** p<0.001). C. Flow cytometry analysis of CCR10 expression in B cell subpopulations in blood of SARS-CoV-2 infected patients (n=25). Samples used in this analysis were collected from day 3 to 27 after symptom onset. Histograms represent medians. P-values were calculated using Wilcoxon test (*** p<0.001). D. Intracellular antibody expression in circulating plasmablasts in blood of SARS-CoV-2 infected patients (n=17) using flow cytometry. Samples used in this analysis were collected from day 2 to 23 after symptom onset. Histograms represent medians. P-values were calculated using Dunn’s multiple comparison test (* p<0.05; *** p<0.001). E. Intracellular IgA versus IgG expression in plasmablasts according to disease duration. Each dot represents one patient. Non-parametric Spearman correlation was calculated.
Fig. 2. Antibody responses kinetics to SARS-CoV-2 proteins. A. Specific IgG, IgA, and IgM against spike-1 receptor binding domain (RBD) and Nucleocapsid protein (NC) were measured using photonic ring immunoassay in 132 patients (clinical characteristics detailed in Tables S2-S3). Antibody levels are expressed as arbitrary units/ml (AU/ml). Cut-off lines are represented as grey dotted lines. The boxplots show medians (middle line) and first and third quartiles and the whiskers indicate minimal and maximal values. P-value was calculated using Dunn’s multiple comparison test (* p<0.05; **p<0.01; ***p<0.001; ****p<0.0001). B. Positive rates of specific serum IgG, IgA, and IgM in 132 patients at different times after symptom onset, from day 1 to 78.
Fig. 3. Neutralizing activity of serum antibodies to SARS-CoV-2. A. Neutralizing activity of 52 sera (dilution 1:40) from 38 SARS-CoV-2 infected patients (see clinical characteristics in Table S1) was determined using a pseudovirus neutralization assay. Orange curve represents significant sigmoidal interpolation (p=0.0082). Grey dotted curves represent 95% confidence intervals. B. Neutralizing activity of 18 sera measured by pseudovirus neutralization assay at different indicated dilutions. Samples used for this analysis were collected between day 6 and 24 after symptom onset. Light blue color corresponds to samples with low IgA neutralization potential. C. Neutralizing activity of purified IgG was measured at indicated concentrations from 18 sera collected between day 6 and day 24 post-symptom onset. Curves were drawn according to non-linear regression. Light blue color corresponds to samples with low IgA neutralization potential. D. Neutralizing activity of purified IgA from paired samples in Fig. 3C. Light blue color corresponds to samples with low IgA neutralization potential. E. Paired purified IgA and IgG IC₅₀ values in samples tested in Figs. 3C and D. P-value was calculated using Wilcoxon test (* p<0.05). F. Comparison of serum anti-RBD IgA (main panel) or IgG (insert) levels measured by photonic ring immunoassay with neutralizing capacity of corresponding purified isotypes measured by pseudovirus neutralization assay. Spearman coefficient (r) and P-value (p) are indicated. G. Neutralizing activity of bronchoalveolar lavages (BAL) collected in 10 SARS-CoV-2 patients between day 4 and 23 after symptom onset (clinical characteristics are detailed in Table S5). Indicated BAL dilutions were tested using pseudovirus neutralization assay. Bronchoalveolar lavages obtained from SARS-CoV-2 negative patients (n=3) showed no neutralization activity (dotted grey lines). Each colored line represents one patient. H. Neutralizing activity and anti-RBD IgA levels (both tested at dilution 1:4) of saliva collected in 10 SARS-CoV-2 patients between day 49 and 73 after symptom onset. Spearman coefficient (r) and P-value (p) are indicated. I. Anti-RBD levels in paired saliva and serum from patients tested in Fig. 3H. P-value was calculated using Wilcoxon test (**p<0.01).
IgA dominates the early neutralizing antibody response to SARS-CoV-2
